The study of weak radiative decays of charmed mesons is still in its developing stage. In the Standard Model (SM), the physics of charm mesons is not generally expected to have new physics (NP) discovery potential. The weak decays of $D$ mesons are also difficult to investigate due to the strong final-state interactions related to QCD. $c \rightarrow u\gamma$ decays can be affected by some contributions coming from the non-minimal supersymmetry, which is a NP scenario. $R_{\rho/\omega}$ could be violated already in the SM framework, while a similar relation for $D_s^+\rightarrow \rho^+\gamma$ radiative decays offers a much better test for $c \rightarrow u\gamma$. Here, we present a sensitivity study of the radiative charm decays $D_s^+\rightarrow \rho^+\gamma$ and $D_s^+\rightarrow K^{*+}\gamma$ with data collected by the Belle II experiment.

The Study of Radiative $D_s$ Decays

N Sushree Ipsita

1. Introduction

In the Standard Model (SM), the physics of charmed mesons is not generally expected to have New Physics (NP) discovery potential because of the relevant CKM matrix elements $V_{cs}$ and $V_{cd}$ are well known and the CP asymmetries and $D^0 - \bar{D}^0$ oscillations are small. Further, the weak decays of $D$ mesons are difficult to investigate due to the strong final state interactions related to QCD. However, it has been pointed out that the oscillations and $c \rightarrow u\gamma$ decays might have some contributions coming from the non-minimal supersymmetry (the NP scenario). Therefore, one can search for NP using $c \rightarrow u\gamma$ transitions. It was suggested that the NP would result in a deviation from $R_{\rho/\omega}$ [2].

$$R_{\rho/\omega} \equiv \frac{\Gamma(D^0 \rightarrow \rho^0/\omega\gamma)}{\Gamma(D^0 \rightarrow \omega\gamma)} = \frac{\tan^2\theta_c}{2} \quad (1)$$

In order to find the best mode to test $c \rightarrow u\gamma$ decay, the ratios between various Cabibbo-suppressed and Cabibbo-allowed radiative decays of charmed mesons are calculated as predicted by the SM. It has been noticed that eq.1 could be violated already in the SM framework because of a large, unknown correction within the SM, while a similar relation for $D_s^+$ radiative decays offers a much better test for $c \rightarrow u\gamma$ [3].

$$R_K \equiv \frac{\Gamma(D_s^+ \rightarrow K^{*+}\gamma)}{\Gamma(D_s^+ \rightarrow \rho^+\gamma)} = \tan^2\theta_c \quad (2)$$

Radiative $D_s$ decays, such as $D_s^+ \rightarrow K^{*+}\gamma$ and $D_s^+ \rightarrow \rho^+\gamma$, have not been observed yet. The theoretical analysis of the $D \rightarrow V\gamma$ transitions was done using a model that combines heavy quark effective theory and the chiral Lagrangian approach and includes symmetry breaking [4]. In addition to the s-channel annihilation and t-channel W exchange, there is a long-distance penguin-like $c \rightarrow u\gamma$ contribution in the Cabibbo-suppressed modes. Its magnitude is determined by the size of symmetry breaking, which was calculated with a vector dominance approach. Although smaller in magnitude, the penguin-like contribution would lead to sizable effects in case of cancellations among the other contributions to the amplitude. Thus, it may invalidate suggested tests beyond the standard model effects in these decays. Figure 1 shows the Feynman diagram of $c \rightarrow u\gamma$ transition

**Figure 1:** Feynman diagram

This model predicts a range of values for the branching ratios predicted for the various $D \rightarrow V\gamma$ modes, as shown in table 1. Here, we present the first experimental study of these modes.

2. Sample Selection

The selection of signal candidates is optimized using simulated samples that have been generated with the EvtGen [6] and Geant packages [7]. We have reconstructed $D_s^+$ from $D_s^+ \rightarrow \rho^+\gamma$ and $D_s^+ \rightarrow K^{*+}\gamma$, where $\rho^+ \rightarrow \pi^0\pi^+$ and $K^{*+} \rightarrow K^0\pi^+$, respectively. The kinematic variable that distinguishes the signal from the background is $\Delta M$. To reduce the combinatorial background, we keep only those candidates that satisfy the criteria: $0.08 \text{ GeV}/c^2 < \Delta M < 0.20 \text{ GeV}/c^2$, where $\Delta M$ is the difference between the reconstructed mass of $D_s^+$ and $D_s^+$ ($\Delta M \equiv M(D_s^*) - M(D_s^+)$). $\pi^0$ veto has been implemented to get rid of the huge background coming from $\pi^0$ decays. We have performed background MC study in which the continuum background is found to be dominant. We employ multivariate analysis (MVA) using the FastBDT package to get rid of uds background. After applying a cut greater than 0.4 (0.5) on MVA for $D_s^+ \rightarrow \rho^+\gamma$ ($D_s^+ \rightarrow K^{*+}\gamma$) decay mode, there is a rejection of 65% (76%) of background from processes such as $e^+e^- \rightarrow u\bar{u}, d\bar{d}, s\bar{s}$ at the cost of 10% (24%) of signal loss, respectively. For $D_s^+ \rightarrow \rho^+\gamma$ decay mode, peaking background is mostly coming from the $D_s^+ \rightarrow \rho^+\eta$, and for $D_s^+ \rightarrow K^{*+}\gamma$, mostly coming from the $D^0 \rightarrow K^0\pi^0$ and $D^0 \rightarrow K^0\eta$ decay modes, respectively. The reconstruction efficiency is found to be 0.5% (3.1%) for $D_s^+ \rightarrow \rho^+\gamma$ ($D_s^+ \rightarrow K^{*+}\gamma$), respectively.

3. Control Sample Study

We utilize the peaking backgrounds $D_s^+ \rightarrow \rho^+\eta \rightarrow \gamma\gamma$, $D_s^0 \rightarrow [D^0 \rightarrow K^0\eta\gamma$ and $D_s^* \rightarrow [D^0 \rightarrow K^0\pi^0]\gamma$ as our control sample to verify the signal extraction procedure and to calibrate possible discrepancies in the signal resolution between data and simulation. Figure 2 shows the 1D unbinned maximum likelihood fit on $\Delta M$ for (a) $D_s^+ \rightarrow \rho^+\eta$ and (b) $D_s^0 \rightarrow K^0\pi^0$ and (c) $D_s^0 \rightarrow K^0\eta$ decay modes, respectively.
4. Signal Extraction

Figure 3: Fitted distribution of $\Delta M$ for (a) $D_s^+ \rightarrow \rho^+\gamma$ (left) and (b) $D_s^+ \rightarrow K^{*+}\gamma$ (right) decay modes, respectively.

We have performed 1D unbinned maximum likelihood fit on $\Delta M$ for (a) $D_s^+ \rightarrow \rho^+\gamma$ and (b) $D_s^+ \rightarrow K^{*+}\gamma$ decay modes, respectively shown in Figure 3. For $D_s^+ \rightarrow \rho^+\gamma$ case, the signal is modeled with the sum of two bifurcated Gaussian with a common mean. The peaking background is modeled with the sum of two bifurcated Gaussian, combinatorial background with third-order Chebyshev Polynomial. For $D_s^+ \rightarrow K^{*+}\gamma$ mode, the signal is modeled with the sum of two bifurcated Gaussian. The peaking backgrounds are modeled with the sum of a Gaussian and a bifurcated Gaussian. The combinatorial background is modeled with third-order Chebyshev Polynomial. All the signal and peaking background parameters are fixed except the Chebyshev Polynomial.

5. Preliminary Results and Outlook

We are expecting 300-400 (20-30) events for $D_s^+ \rightarrow \rho^+\gamma$ ($D_s^+ \rightarrow K^{*+}\gamma$) decay modes using $10^{-4}$ ($10^{-5}$) branching fraction corresponding to an integrated luminosity of 921 fb$^{-1}$.
